

FUNDAMENTAL PLANE OF BLACK HOLE ACTIVITY IN QUIESCENT REGIME

FU-GUO XIE¹ AND FENG YUAN¹

Draft version January 24, 2017

ABSTRACT

A correlation among the radio luminosity (L_R), X-ray luminosity (L_X), and black hole mass (M_{BH}) in active galactic nuclei (AGNs) and black hole binaries is known to exist and is called the “Fundamental Plane” of black hole activity. Yuan & Cui (2005) predicts that the radio/X-ray correlation index, ξ_X , changes from $\xi_X \approx 0.6$ to $\xi_X \approx 1.2 - 1.3$ when L_X/L_{Edd} decreases below a critical value $\sim 10^{-6}$. While many works favor such a change, there are also several works claiming the opposite. In this paper, we gather from literature a largest quiescent AGN (defined as $L_X/L_{Edd} \lesssim 10^{-6}$) sample to date, consisting of 75 sources. We find that these quiescent AGNs follow a $\xi_X \approx 1.23$ radio/X-ray relationship, in excellent agreement with the Yuan & Cui prediction. The reason for the discrepancy between the present result and some previous works is that their samples contain not only quiescent sources but also “normal” ones (i.e., $L_X/L_{Edd} \gtrsim 10^{-6}$). In this case, the quiescent sources will mix up with those normal ones in L_R and L_X . The value of ξ_X will then be between 0.6 and ~ 1.3 , with the exact value being determined by the sample composition, i.e., the fraction of the quiescent and normal sources. Based on this result, we propose that a more physical way to study the Fundamental Plane is to replace L_R and L_X with L_R/L_{Edd} and L_X/L_{Edd} , respectively.

Subject headings: accretion, accretion discs – black hole physics – galaxies: active – methods: statistical

1. INTRODUCTION

There are many observational evidences in black hole (BH) X-ray binaries (BHBs) and active galactic nuclei (AGNs) for the coupling between the collimated relativistic jet and the accretion flow. One such evidence comes from Corbel et al. (2003) and Gallo et al. (2003), who discovered a remarkably tight correlation between radio (monochromatic, $L_R = \nu L_\nu$, at, e.g. 5 or 8.5 GHz) and X-ray (at 2–10 keV; hereafter L_X) luminosities in BHBs during their hard states (see Corbel et al. 2013 for latest summary). This correlation was later extended to include low-luminosity AGNs (LLAGNs). With the impact of black hole mass M_{BH} taken into account, Merloni et al. (2003, hereafter M03) found that, $\log L_R = 0.6 \log L_X + 0.78 \log M_{BH} + 7.33$, with a scatter of $\sigma_R = 0.88$ dex. Here (and throughout this paper) the luminosities and BH mass are, respectively, in units of erg s^{-1} and M_\odot . We refer this relationship as the *original/standard* M03 “Fundamental Plane” (hereafter FP) of black hole activity (for later work, see e.g., Falcke et al. 2004; Kording et al. 2006; Merloni et al. 2006; Wang et al. 2006; Panessa et al. 2007; Li et al. 2008; Gültekin et al. 2009, hereafter G09; Plotkin et al. 2012; Younes et al. 2012; Dong & Wu 2015; Panessa et al. 2015; Fan & Bai 2016; Liu, Han & Zhang 2016; Nisbet & Best 2016).

Yuan, Cui & Narayan (2005) have proposed a coupled accretion–jet model for LLAGNs and BHBs (see Yuan & Narayan 2014 for a review). In this model, unless the system is extremely faint, the thermal gas in a hot accretion flow is responsible for the X-ray emission and the relativistic power-law distribution electrons in a jet produce the radio emission. Yuan & Cui (2005, hereafter YC05) show that the FP can be explained naturally in this model (see also M03; Heinz & Sunyaev 2003; Heinz 2004; Xie & Yuan 2016), i.e. it is a direct consequence of a tight relationship between mass inflow/accretion rate and mass ejection rate (YC05; Xie &

Yuan 2016). The scatter of the correlation, on the other hand, may reflects the (combination of) effects of other parameters, e.g., the intrinsic variability in radio and X-rays, the BH spin (Miller et al. 2009; Narayan & McClintock 2012), the strength of magnetic field (Blandford & Znajek 1977; Sikora et al. 2007), the Doppler beaming effect (Li et al. 2008, but see van Velzen & Falcke 2013), the angular momentum of the accreting gas (Cao 2016) and the environment (van Velzen & Falcke 2013).

After the discovery of the original M03 FP, several notable complexities are revealed over the past decade. First, AGNs with different radio loudness seem to follow relationships that are different in both normalization and correlation slope (e.g., Wang et al. 2006; Li et al. 2008; de Gasperin et al. 2011). Secondly, long-term quasi-simultaneous monitoring on individual sources find that, some sources do not follow the slope predicted by the original M03 FP during their fluctuations in luminosities, and they can be classified as outliers (for BHBs, see e.g. Xue & Cui 2007; Coriat et al. 2011, and Corbel et al. 2013 for a recent summary; for AGNs, see e.g. Bell et al. 2011; King et al. 2013; Xie et al. 2016). These outliers, *individually*, seem to follow a hybrid radio/X-ray correlation, i.e. $L_R \propto L_X^{-1.3}$ when L_X is high (see also Gallo et al. 2012; Dong, Wu & Cao 2014; Panessa et al. 2015; Qiao & Liu 2015), $L_R \propto L_X^0$ when L_X is moderately low, and can recover the original M03 FP when L_X is much lower. The hybrid correlation is most evident in BHB H1743–322 (Coriat et al. 2011) and LLAGN NGC 7213 (Bell et al. 2011; Xie et al. 2016).

The third complexity, which is the focus of this work, is whether or not the AGNs with extremely low luminosities, i.e. the so-called “quiescent” AGNs (defined as sources with $L_X/L_{Edd} \lesssim 10^{-6}$, here $L_{Edd} = 1.3 \times 10^{46} M_{BH}/10^8 M_\odot \text{ erg s}^{-1}$ is the Eddington luminosity), follow the original M03 FP. YC05 shows that the answer should be “no”. The reason is that in the accretion–jet scenario, the origin of the X-ray emission in quiescent AGNs is different to that of normal LLAGNs (defined as sources with $L_X/L_{Edd} \gtrsim 10^{-6}$), i.e.

¹ Key Laboratory for Research in Galaxies and Cosmology, Shanghai Astronomical Observatory, Chinese Academy of Sciences, 80 Nandan Road, Shanghai 200030, China; fgxie@shao.ac.cn, fyuan@shao.ac.cn

it originates from jet instead of hot accretion flow (YC05). Physically, this is because the both the hot accretion flow and the jet emit X-ray emission, but the dependence of X-ray radiation from the hot accretion flow on the accretion rate is less sensitive compared to that from the jet. Thus with the decrease of accretion rate (or equivalently luminosity), the radiation from the jet will catch up with that from the accretion flow and become dominant below a critical luminosity $L_{X,\text{crit}}/L_{\text{Edd}} \approx 10^{-6}$ (see also Fender, Gallo & Jonker 2003). Moreover, because of the change of the X-ray origin from a hot accretion flow to a jet, YC05 predicts that the quiescent accretion systems will follow a steeper relationship between radio and X-rays (see also Heinz 2004; Gardner & Done 2013), i.e., the FP of faint accretion systems is revised to (YYH09), $\log L_R = 1.23 \log L_X + 0.25 \log M_{\text{BH}} - 13.45$. Hereafter we will refer to this relationship as the YC05 FP.

We note that the value of the critical luminosity $L_{X,\text{crit}}$ depends on detailed parameters that control the properties of accretion flow and/or jet. The $L_{X,\text{crit}}$ value obtained in YC05 is for the “general” sources. If for some reason (e.g., Doppler beaming) the radiation from the jet is very strong in some sources, the critical luminosity can become significantly larger. This is the case of radio loud sources (e.g., Wang et al. 2006; Li et al. 2008; de Gasperin et al. 2011). In this work, we aim at “general” sources.

The YC05 predictions have been confirmed by many observational and theoretical works (see review by Yuan & Narayan 2014), both of AGNs (e.g., Pellegrini et al. 2007; Wu, Yuan & Ho 2007; Wrobel, Terashima & Ho 2008; Yuan, Yu & Ho 2009, hereafter YYH09; de Gasperin et al. 2011; Younes et al. 2012; Li, Yuan & Xie 2016) and BHBs (e.g., Pszota et al. 2008; Plotkin et al. 2013; Reynolds et al. 2014; Xie, Yang & Ma 2014; Yang et al. 2015a). For example, YYH09 did a statistical analysis based on a sample consisting of 22 quiescent AGNs. They found $\xi_X = 1.22 \pm 0.02$, in excellent agreement with YC05 prediction.

However, there are also claims in literature on an universal FP extending down to quiescent systems, without any steepening pattern. For example, the three BHBs with radio and X-ray observations during their quiescent states are claimed to follow the original M03 FP at low X-ray luminosities (Gallo et al. 2006, 2014; Corbel, Koerding & Kaaret 2008; Corbel et al. 2013). For AGNs, recently Dong & Wu (2015, hereafter DW15) selected from the flux-limited Polmar survey a sample of 73 AGNs (Sgr A* also included), and combine with a large sample of data points of BHBs, to investigate the FP jointly from sub-Eddington to quiescent systems. They claim that those with $L_X \lesssim L_{X,\text{crit}}$ (24 AGNs under a detailed definition of $L_{X,\text{crit}}$, cf. DW15) seem to be roughly consistent the original M03 FP. As discussed in detail later in Sections 5.3 & 5.4, we argue their analysis and conclusion have some problems.

In this work, the FP of quiescent systems is re-examined. Because the aim is to check the YC05 prediction, following YYH09, we exclude normal LLAGNs and focus on quiescent AGNs only. In order to reduce the contamination of the host galaxy, we restrict ourselves to observations that have sufficiently high spatial resolution and sensitivity. This paper is organised as follows. We describe our sample compilation (75 sources in total, to our knowledge the largest quiescent AGN sample to date) in Section 2. We then introduce the statistical analysis method in Section 3. Subsequently we present the fitting results in Section 4. Sections 5 and 6 are devoted to discussions and a brief summary respectively.

2. THE SAMPLE OF QUIESCENT/FAINT AGNS

We gather from literature a sample of quiescent/faint AGNs with measurements in their black hole mass, nuclei radio (at 5 GHz) and X-ray (2-10 keV) luminosities. Since most of our targets are weak nuclei at the center of normal galaxies, contamination of emission from their host galaxy, i.e. the radio emission due to residual star formation or supernovae remnants in the nuclei region of the host galaxy, or extended/elongated radio emission from mini-lobes if the jet is spatially resolved (cf. discussions in Nyland et al. 2016), could be of vital importance. In order to discriminate these possible contaminations, we select data which are observed with arcsec (or even higher, e.g., *XMM-Newton* and *Chandra* for X-rays, and Very Large Array [VLA] for radio.) spatial resolution. For sources that have several observations, we prefer data with higher spatial resolution. Moreover, for sources with extended radio morphologies, we only consider the nuclei component, i.e. the emission of the compact jet. Considering the strong fluctuations in AGN activity, we argue that only this compact radio component relates directly to the *current* nuclei activity (shown in X-rays) of the AGNs. We also note that for the X-rays of NGC 3115, only the compact component is adopted (Wong et al. 2014).

The BH mass in these systems is mostly derived based on the empirical $M_{\text{BH}}-\sigma$ relationship (cf. Kormendy & Ho 2013 for review of various ways to estimate M_{BH}), whose uncertainty is normally $\sigma_M \approx 0.3$. More reliable M_{BH} measurements, such as those derived from kinematics or reverberation-mapping, will be adopted if exist, cf. references in Table 1 for details. Besides, in order to convert the observed flux to luminosity, the luminosity distance d_L should be given in advance. Because of the luminosity constraint, most of the sources in our sample have $d_L \lesssim 50$ Mpc. Consequently, most of our sources have redshift-independent distance measurements. For most of these sources, the distances adopted in this work are from Tully et al. (2013), where we select distances constrained through the surface brightness fluctuation (SBF) method. For the rest few sources that lack redshift-independent distance measurements, we derive d_L from redshift based on the Planck2015 flat cosmology (Planck Collaboration et al. 2016), with $H_0 = 67.8 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and $\Omega_M = 0.308$.

The main selection criteria of our sample compilation comes from the X-ray luminosity constraint, i.e. we require the X-ray Eddington ratio $L_X/L_{\text{Edd}} \lesssim 10^{-6}$, a critical luminosity below which the accretion-jet model predicts a jet origin of the X-ray emission (YC05; YYH09). Considering the uncertainties in the measurements of M_{BH} , practically this criteria is slightly weakened to $L_X/L_{\text{Edd}} < 10^{-5.7}$ (cf. the X-axis range of Fig. 1). There is one notable exception – we exclude from our sample Sgr A*, whose $L_X/L_{\text{Edd}} \sim 10^{-11}$ (in its quiescent state, cf. Fig. 6). High-resolution radio observations suggest the non-existence of elongated/collimated jet in this system during its quiescent state (at $\sim 10 R_s$ level, where R_s is the Schwarzschild radius of BH, see e.g., Shen et al. 2005; Doeleman et al. 2008),² and theoretically the low-frequency radio emission (e.g. at 5 GHz) originates from the relativistic power-law distribution electrons within the hot accretion flow itself (Yuan, Quataert & Narayan 2003), instead of the jet. Moreover, the X-

² Note that, as an independent approach, the jet in quiescent state of Sgr A* is recently ruled out by the reliable measurement of the Faraday Rotation Measure at submillimeter wavelength (Li, Yuan & Wang 2014).

ray emission in Sgr A* is dominated by diffuse gas around $\sim 10^5 R_s$ (e.g. [Baganoff et al. 2003](#); [Wang et al. 2013](#)), unlike that in other normal LLAGNs where it originates from nuclei $< 50 R_s$ regions (e.g., [Fabian et al. 2009](#); [Emmanoulopoulos et al. 2014](#)). Detailed discussion on Sgr A*, including its flare state, will be given later in Section 5.3.2.

Fig. 1.— Distribution of black hole mass (in unit of M_\odot) as a function of X-ray Eddington ratio (L_X/L_{Edd}). The two red solid curves mark the boundaries of the (quasi-) M_{BH} -free subsample, i.e. $\log M_{\text{BH}} = 8.1, 9.1$, and the black dashed curve shows the average BH mass of this subsample, $\log \langle M_{\text{BH}} \rangle = 8.71$. The blue filled circles represent sources with firm detections in L_R and L_X , the orange open circles and red arrows show sources whose L_R and L_X are, respectively, upper limit constraints. The dark grey arrows are sources whose L_R and L_X are both upper limit constraints. Several notable sources are labelled in green.

As listed in Table 1 and shown in Fig. 1, our final sample includes 75 sources, mainly selected from previous compilations, e.g., M03; [Nagar, Falcke, & Wilson \(2005\)](#); [Hardcastle et al. \(2009\)](#); [Ho \(2009\)](#); [Ho et al. \(2009\)](#); [YYH09](#); [Pellegrini \(2010\)](#); [DW15](#) and [Nyland et al. \(2016\)](#). As shown in Fig. 1, to our knowledge this is the largest quiescent AGN sample to date, in which 5 sources have $L_X/L_{\text{Edd}} \lesssim 10^{-9}$. In this sample, 58 sources have firm detections in both radio and X-rays (blue filled circles in Fig. 1). 8 sources have upper limit constraints in radio but firm detections in X-rays (orange open circles in Fig. 1, and orange arrows in the rest figures), while 4 sources have firm detections in radio but only upper limit constraints in X-rays (red arrows in Fig. 1). The rest 5 sources only have upper limit constraints in both radio and X-rays (grey arrows in Fig. 1). As shown in Fig. 1, this quiescent AGN sample covers a large dynamical range in both radio and X-ray Eddington ratios, i.e. $10^{-14} < L_R/L_{\text{Edd}} < 10^{-7}$ (cf. Fig. 6 below) and $10^{-10} < L_X/L_{\text{Edd}} < 10^{-5.7}$. The BH mass of most sources is between $10^{-7.5} M_\odot$ and $10^{-9} M_\odot$, with a few exceptions, e.g., $M_{\text{BH}} = 10^{5.16} M_\odot$ for NGC 404 ([Ho 2009](#)) and $M_{\text{BH}} = 10^{6.4} M_\odot$ for M32 ([Kormendy & Ho 2013](#)). We emphasize that the nuclei of M31, with $L_R/L_{\text{Edd}} = 10^{-14.0}$ and $L_X/L_{\text{Edd}} = 10^{-10.2}$ ([Garcia et al. 2010](#)), represents the faintest (in Eddington unit) source in our sample.

With the fact that the LLAGNs are expected to vary moderately on timescale of months to years ([Ho & Peng 2001](#); [Ho 2008](#)), the uncertainties of the data mainly comes from the non-simultaneity between radio and X-rays (Note that additionally, the time delay between the two wavebands should be corrected, cf. Section 5.1). Considering the systematic and the observational uncertainties, we take isotropic uncertainties with $\sigma_R = \sigma_X = \sigma_M = 0.3$ dex,

following M03 and G09.

3. FITTING METHOD

We consider the following linear (in logarithmic space) relationship among three quantities, e.g., L_R (in unit of erg s^{-1}), L_X (in unit of erg s^{-1}) and M_{BH} (in unit of M_\odot),

$$\log L_R = \xi_X \log L_X + \xi_M \log M_{\text{BH}} + c. \quad (1)$$

For our statistical analysis, we adopt the Markov chain Monte Carlo (MCMC) Bayesian analysis (cf. e.g. [Kelly 2007](#); [Foreman-Mackey et al. 2013](#), hereafter Bayesian approach.) to derive the best-fit parameters and their corresponding uncertainties (see e.g., [Plotkin et al. 2012](#)). For this approach, we take the Python routine Emcee ([Foreman-Mackey et al. 2013](#)) ver. 2.2.1, which is based on the affine invariant MCMC ensemble sampler method ([Goodman & Weare 2010](#)). Besides, we assume the intrinsic scatter of the FP is of Gaussian distribution. Moreover, since L_X (or L_X/L_{Edd}), L_R (or L_R/L_{Edd}) and M_{BH} are symmetric physical quantities during the modelling, we in practice set the model prior probability function $p(\xi_X, \xi_M, c)$ to ([VanderPlas 2014](#)),

$$p(\xi_X, \xi_M, c) = (1 + \xi_X^2)^{-3/2} (1 + \xi_M^2)^{-3/2} \quad (2)$$

We note that the multivariate correlation coefficients shown in several influential works (among others see e.g., M03 and G09) are derived through minimization of the following statistics (hereafter least χ^2 approach),

$$\chi^2 = \sum \frac{(\log L_R - \xi_X \log L_X - \xi_M \log M_{\text{BH}} - c)^2}{\sigma_R^2 + \xi_X^2 \sigma_X^2 + \xi_M^2 \sigma_M^2}. \quad (3)$$

Although this method can provide reasonable regression coefficients (cf. [Fasano & Vio 1988](#)), there are indeed some concerns (e.g., [Plotkin et al. 2012](#)). For the sake of direct comparison to those previous works, we also provide results under this approach, but our discussions will be mainly based on results derived through the Bayesian regression analysis. Technically we use the Python routine `kmpfit`³ of the Kapteyn package ver. 2.3 ([Terlouw & Vogelaar 2012](#)), in which the C implementation of `mpfit` ([Markwardt 2009](#)) is adopted.

4. RESULTS

In this section, we present the numerical results based on different approaches. Section 4.1 considers the sample consisting of all the quiescent AGNs (72 sources), where both the Bayesian and the least χ^2 methods are adopted (cf. Section 3 above). Section 4.2 represents the results based on a subsample with similar black hole mass (42 sources). This is because we want to focus on the value of ξ_X so we hope to eliminate any possible contamination by the black hole mass. We find a convergence in both methods, i.e. $\xi_X \sim 1.2$ – 1.4 .

4.1. The FP of quiescent AGNs

Here we investigate the linear relationship among $\log(L_R)$, $\log(L_X)$ and $\log(M_{\text{BH}})$, following the methodologies described in Section 3. We first consider a sub-sample of 58 sources, which have firm detections in both radio and X-rays (hereafter firm-detection subsample). We find that, they follow a FP with parameters constrained as,

$$\xi_X = 1.09_{-0.07}^{+0.07}, \quad \xi_M = 0.70_{-0.11}^{+0.12}, \quad c = -11.61_{-2.25}^{+2.19} \quad (4)$$

³ <https://github.com/josephmehring/kmpfit>

FIG. 2.— The Fundamental Plane of quiescent AGNs. The red solid and dashed curves represent the Bayesian regression analysis result (cf. Eq. 6) and its scatter, respectively. For comparison, we show the original M03 FP by the two grey long-dashed curves, with M_{BH} fixed to $10^9 M_{\odot}$ (upper) and $10^8 M_{\odot}$ (lower). The meaning of the symbols is the same as that in Fig. 1 (note that the orange arrows here are the same as the orange circles in Fig. 1). Several notable sources are labelled in green. Additionally, Sgr A* in its quiescent and flare states, is shown by black asterisks for the purpose of comparison, see Sec. 5.3.2 for details.

FIG. 3.— The one and two dimensional projections of the posterior probability distributions of the fitting parameters based on Bayesian MCMC analysis of the whole quiescent AGN sample, cf. Eq. 6. The three dashed curves mark the location of the best-fit value, and the corresponding 1σ uncertainties.

under the Bayesian regression analysis, and

$$\xi_X = 1.12^{+0.07}_{-0.07}, \quad \xi_M = 0.82^{+0.11}_{-0.11}, \quad c = -13.60^{+2.29}_{-2.29}, \quad (5)$$

under the least χ^2 approach. Obviously the firm-detection subsample shows a steeper radio/X-ray correlation slope compared to that of the original FP.

We then analyse the whole quiescent AGN sample. Under the Bayesian approach, the fitting parameters read,

$$\xi_X = 1.23^{+0.07}_{-0.07}, \quad \xi_M = 0.63^{+0.12}_{-0.12}, \quad c = -16.53^{+2.11}_{-2.19}, \quad (6)$$

with the intrinsic scatter in $\log L_R$ to be $\sigma_R = 0.81$ dex, and under the least χ^2 method the fitting parameters read,

$$\xi_X = 1.30^{+0.07}_{-0.07}, \quad \xi_M = 0.57^{+0.10}_{-0.10}, \quad c = -18.53^{+2.19}_{-2.19}, \quad (7)$$

with the intrinsic scatter in $\log L_R$ to be $\sigma_R = 0.82$ dex.

The radio/X-ray correlation slope derived above (e.g. Eqs. 6&7) is clearly different, at $> 6\sigma$ confidence level, from that of the original M03 FP, whose $\xi_X \approx 0.6 \pm 0.1$ (see also Corbel et al. 2013 for summary of this relationship in BHBs). This FP is in good agreement (in ξ_X) with the prediction of YC05 and the result of YYH09 based on a limited quiescent AGN sample. We show the Bayesian regression analysis result (cf. Eq. 6) as the red solid curve in Fig. 2. The two red dashed curves represent the intrinsic 1σ scatter of the best-fit result. For comparison, we also show the original M03 FP by the two black long-dashed curves, where the black hole mass is fixed to $10^8 M_{\odot}$ and $10^9 M_{\odot}$, respectively, for the lower and the upper curves. Fig. 3 shows one and two dimensional projections of the posterior probability distributions of Bayesian MCMC fitting parameters, where the three dashed curves mark the location of the best-fit values, and the corresponding 1σ uncertainties (cf. Eq. 6).

From Fig. 2, there are several points worth further emphasis. First, considering the moderately large scatter in the observational data, the deviation to the original M03 FP (cf. the long-dashed curves) is most evident in M31 (see also Fig. 5 below and Wu et al. 2013), which has lowest L_X/L_{Edd} and L_R/L_{Edd} in our sample. The other sources, on the other hand, are in rough agreement with the original M03 FP (see also Fig. 5 below). In this sense, we urge to devote more

efforts on sources whose X-ray Eddington ratio $L_X/L_{\text{Edd}} \lesssim 10^{-9.5}$. These sources are of crucial importance in confirming the deviation to the original FP, as well as the existence of a new YC05-type FP in these faint/quiescent AGNs. Secondly, the radio/X-ray correlation slope ξ_X in quiescent AGNs can be constrained from a sample which includes quiescent AGNs only. If instead the sample also includes numerous brighter sources, the new steep correlation will become invisible. We will discuss these two issues further in Section 5.3.

^b VLA observed at 1.4 GHz; The flux is convert to that at 5 GHz with a flat radio spectrum assumption, i.e. $\alpha = -0.4$ where $F_{\nu} \propto \nu^{-\alpha}$.

^c Only the compact component of Very Long Baseline Array (VLBA) observation (at 8.4 GHz) is considered here. The flux is convert to that at 5 GHz with the assumption $\alpha = -0.4$.

4.2. (Quasi-) M_{BH} -free subsample: the radio/X-ray correlation index ξ_X

The key point of the YC05 prediction is the change of the radio/X-ray correlation index ξ_X . Therefore, the best way to examine this prediction is to study the correlation only between L_{R} and L_{X} , without the possible “contamination” of black hole mass M_{BH} . This is because we have more freedom in the fitting among three quantities L_{R} , L_{X} and M_{BH} , thus it is difficult to determine the value of ξ_X precisely.

Following de Gasperin et al. (2011) and DW15 we create a subsample of sources with similar M_{BH} , but has a large dynamical range in X-ray luminosity (in Eddington unit). For simplicity we name it a (quasi-) M_{BH} -free subsample. As shown in Fig. 1, we select sources with M_{BH} in the range $10^{8.1} - 10^{9.1} M_{\odot}$ (one dex in M_{BH} , the boundaries are shown as two red solid curves in this plot). The boundaries are chosen so that the subsample will have largest dynamical range in $L_{\text{X}}/L_{\text{Edd}}$, i.e. $10^{-10} < L_{\text{X}}/L_{\text{Edd}} < 10^{-5.7}$. This M_{BH} -free subsample includes 42 sources, among which 34 have firm detections in both radio and X-rays. The average black hole mass of this subsample is $\langle M_{\text{BH}} \rangle = 10^{8.71} M_{\odot}$.

This M_{BH} -free subsample can be used to explore the radio/X-ray correlation, and provide direct constraints on the correlation slope ξ_X . A linear fit between $\log L_{\text{R}}$ and $\log L_{\text{X}}$ of this M_{BH} -free subsample under the Bayesian method reads (cf. Sec. 3, but note that the quantity M_{BH} is omitted during the modelling.),

$$\log L_{\text{R}} = 1.36_{-0.06}^{+0.07} \log L_{\text{X}} - 16.38_{-2.65}^{+2.48}, \quad (8)$$

FIG. 4.— The radio/X-ray correlation of the M_{BH} -free subsample. The black solid curve, with $\xi_X = 1.36$, represents the fitting of this subsample, cf. Eq. 8. For comparison, we also show the $\xi_X = 1.23$ FP of the whole sample (the red dashed curve), and the original M03 FP (the grey long dashed curve), both of which have M_{BH} fixed to $\langle M_{\text{BH}} \rangle$. The meaning of the symbols is the same as that in Fig. 2. In addition, the red open triangles and the green open squares are respectively, the 14 normal LLAGNs selected from DW15 and the 10 AGNs selected from M03, both under the same M_{BH} constraint. They are shown here as representative of normal LLAGNs that follow the shallower M03 FP.

and under the least χ^2 method reads,

$$\log L_R = 1.45^{+0.07}_{-0.07} \log L_X - 19.59^{+2.83}_{-2.83}. \quad (9)$$

We show the Bayesian fitting result as the black solid curve in Fig. 4. Note that the radio/X-ray correlation slope here is clearly different, at $> 7\sigma$ confidence level, from that of the original M03 FP (black long-dashed curve in Fig. 4, with M_{BH} set to $\langle M_{\text{BH}} \rangle$). For comparison, we also plot in Fig. 4 the $\xi_X = 1.23$ FP of the whole quiescent AGN sample (the red dashed curve), with M_{BH} also fixed to $\langle M_{\text{BH}} \rangle$. Apparently its difference to Eq. 8 is insignificant.

In Fig. 4, we additionally show 14 normal LLAGNs (red open triangles) selected from DW15 and the 10 AGNs (green open squares, hereafter the M_{BH} -selected M03 AGNs.) selected from M03, both under the same M_{BH} constraint. They are shown here as representative of normal LLAGNs and normal AGNs that follow the shallower M03 FP. It is evident from this plot that quiescent AGNs follow a different, steeper, radio/X-ray correlation, compared to the normal LLAGNs and normal AGNs.

Because the physics of accretion and radiation is more relevant to the quantities in Eddington unit rather than its absolute values (such as mass accretion rate and luminosity), we further try to find a linear relationship between $\log(L_R/L_{\text{Edd}})$ and $\log(L_X/L_{\text{Edd}})$ for this M_{BH} -free subsample. Assuming the uncertainty of each quantity is still 0.3 dex, the fitting can be read as,

$$\log(L_R/L_{\text{Edd}}) = 1.35^{+0.07}_{-0.07} \log(L_X/L_{\text{Edd}}) + 0.49^{+0.53}_{-0.50} \quad (10)$$

under the Bayesian statistics, and

$$\log(L_R/L_{\text{Edd}}) = 1.43(\pm 0.08) \log(L_X/L_{\text{Edd}}) + 1.13(\pm 0.57) \quad (11)$$

under the least χ^2 approach. Finally a linear fitting between $\log(L_R/L_{\text{Edd}})$ and $\log(L_X/L_{\text{Edd}})$ of the whole sample can be derived as, $\log(L_R/L_{\text{Edd}}) = 1.48^{+0.07}_{-0.07} \log(L_X/L_{\text{Edd}}) + 1.13^{+0.51}_{-0.51}$, where the Bayesian approach is adopted. This result is consistent with that derived based on the M_{BH} -free subsample.

5. DISCUSSIONS

5.1. Uncertainties of the observational data

We first discuss the uncertainties of the observational data, i.e. σ_R and σ_X .

In quiescent AGNs (and normal AGNs also), emission at different wavebands likely correlates with considerable time delays. For one example, Bell et al. (2011) found a ~ 40 -d time delay of radio (at ~ 5 GHz) to X-rays in the LLAGN NGC 7213. Thus, in order to explore the “intrinsic”, physically-connected FP, a correction of the radio/X-ray timelag should be applied. However, in practice such correction is almost impossible for AGNs, as it requires long-term intense coordinated monitoring in radio and X-rays on individual sources.⁴ Moreover, the monitoring should also be able to capture at least one “outburst” in each AGN, in order to have a reliable measurement of the timelag. With these obstacles/challenges, to date very few AGNs have such intense monitoring (see e.g. Bell et al. 2011; King et al. 2013 for such monitoring in AGNs). The time interval between radio and X-rays for the data shown in Table 1 is typically of order of months to years.

The AGNs are variable, with variability amplitude possibly as high as $\sim 100\%$ on time-scales shorter than the time interval of observations (Ho & Peng 2001). Such uncertainty dominates over the actual observational uncertainties in the fluxes (or luminosities; L_R and L_X) of individual observation reported in literature. Admittedly different estimations will result in somewhat different fitting results (Körding et al. 2006). There are several estimations on the systematical uncertainties of the observed fluxes (e.g. Körding et al. 2006, DW15), and we adopt isotropic ones, following M03 and G09. DW15 adopted a slightly smaller scatter in radio luminosities, i.e. $\sigma_R = 0.2$ dex (Ho & Peng 2001), compared to that in X-rays. With this modification to the whole quiescent AGN sample, we carry out Bayesian regression analysis and find that,

$$\xi_X = 1.09^{+0.07}_{-0.07}, \quad \xi_M = 0.70^{+0.12}_{-0.11}, \quad c = -11.61^{+2.19}_{-2.25}. \quad (12)$$

Note that this result is consistent with a steeper radio/X-ray correlation for quiescent AGNs (cf. Eq. 6), and disagrees with the claim of a universal FP from sub-Eddington AGNs to quiescent AGNs.

5.2. impact of Fanaroff-Riley Is and the dimmest M31 on the FP derived

It has been known for years that radio-loud sources systematically follow a steeper radio/X-ray correlation (e.g., Li et al. 2008; de Gasperin et al. 2011; DW15). There are 11 sources in our quiescent AGN sample that belong to Fanaroff-Riley (FR, Fanaroff & Riley 1974) Type Is, which are generally radio-loud. One concern is that, the FP derived above (cf. Eq. 6) may be biased by these sources. To examine the impact of FR Is, we carry out a Bayesian regression analysis to a sub-sample (consist 64 sources) that excludes those FR Is, and the fitting coefficients are,

$$\xi_X = 1.18^{+0.08}_{-0.07}, \quad \xi_M = 0.57^{+0.12}_{-0.11}, \quad c = -14.06^{+2.48}_{-2.59}. \quad (13)$$

⁴ Note that, the radio/X-ray timelag is considerably small in BHBs. Consequently, it is crucial to use (quasi-)simultaneous radio and X-ray observations to explore the radio/X-ray correlation in BHBs. Additional timelag correction is usually not necessary for the BHB cases.

Obviously, it is consistent with the YC05 FP, and disagrees with the M03 FP.

Another concern is that, the FP derived in this work is biased by the dimmest LLAGN in our sample M31 ($L_X/L_{\text{Edd}} \sim 10^{-10}$), since the deviation to M03 FP is insignificant for most of the sources in our sample, cf. Fig. 2. We argue this is actually a misunderstanding, since the radio/X-ray correlation slope can already be determined statistically by abundant other quiescent AGNs. We demonstrate this by applying the Bayesian analysis to a subsample that further excludes M31 (63 sources in total). The correlation coefficients are,

$$\xi_X = 1.12^{+0.08}_{-0.08}, \quad \xi_M = 0.61^{+0.12}_{-0.12}, \quad c = -12.01^{+2.69}_{-2.75}, \quad (14)$$

consistent with the expectation of a YC05 FP in these systems.

5.3. Comparison with previous works

Most of the work in literature on the fundamental plane of black hole activity bias towards moderately brighter systems (e.g. M03; Falcke et al. 2004; K rding et al. 2006; Li et al. 2008; G09; Fan & Bai 2016; Nisbet & Best 2016), thus are irrelevant to this work. In this section we discuss the relation of our work to some of the related works published in recent years, i.e. those include the quiescent accretion systems.

5.3.1. BHBs in their quiescent states: Gallo et al. (2006, 2014); Corbel, Koerding & Kaaret (2008)

In our work, we exclude from the sample data points of BHBs in their quiescent states.

Currently there are three BHBs with reported observations in both radio and X-rays during their quiescent states, e.g. A 0620-00 (Gallo et al. 2006), V404 Cyg (Corbel, Koerding & Kaaret 2008) and XTE J1118+480 (Gallo et al. 2014). It is claimed that these sources in their quiescent state follow the extension of the original $\xi_X \approx 0.6$ FP (Gallo et al. 2006; Corbel, Koerding & Kaaret 2008; Gallo et al. 2014). We argue that the claim of original FP down to quiescent states in BHBs is not robust as claimed. The reasons are as follows (see also Yuan & Narayan 2014; Xie & Yuan 2016). First, A 0620-00 only have observations in quiescent state, but lacks data in hard state. Secondly, V404 Cyg is still too bright, with $L_X \sim 10^{-6.8} L_{\text{Edd}}$, to show clear deviation to the original FP⁵. Finally, the radio detection of XTE J1118+480 at $L_X \sim 10^{-8.5} L_{\text{Edd}}$ is admittedly marginal, at 3σ level.

Moreover, we note that since the correlation is established in a statistical sense. Few individual sources that do not follow the new correlation can not be taken to argue against the existence and correctness of the new relationship. For example, we note that there also exist some ‘‘outliers’’ of the original correlation, as we introduce in *Introduction*.

5.3.2. Sgr A* in quiescent and flare states

For the AGN sample in literature, there is one source, i.e. Sgr A*, that deserves special discussion. This source, with $M_{\text{BH}} = 4.30 \times 10^6 M_\odot$ (Genzel, Eisenhauer & Gillessen 2010), has been included in most previous studies on FP. However, as emphasised in Section 2, there are compelling, independent pieces of evidence against the existence of jet

in Sgr A* during its quiescent state (e.g. Shen et al. 2005; Doeleman et al. 2008; Li, Yuan & Wang 2014), i.e. it does not satisfy the ‘‘existence of jet’’ prerequisite in the study of FP thus should be excluded from the sample. During the quiescent state of Sgr A*, the low-frequency radio emission likely originate from the non-thermal electrons of the hot accretion flow, while the X-ray emission is the bremsstrahlung radiation by diffuse gas around $\sim 10^5 R_s$ (see Baganoff et al. 2003; Yuan, Quataert & Narayan 2003; Wang et al. 2013 and references therein). As shown by the leftmost black asterisk in Fig. 5, we find that, Sgr A* in its quiescent state agrees with the M03 FP (only a coincidence from our point of view), but disagrees with the new $\xi_X \approx 1.23$ FP, as it is more than three orders of magnitude brighter in L_R at the given L_X (see also Markoff 2005).

Sgr A* undergoes numerous flares, which are observed in sub-millimeter, infrared and X-rays (e.g., Baganoff et al. 2003; Neilsen et al. 2013 and references therein). These flares usually last 0.1 – 1 hr (Yusef-Zadeh et al. 2006; Neilsen et al. 2013), indicating that they are from nuclear regions of Sgr A*. During these flares, the luminosities are enhanced by a factor as much as $\sim 10\%$ in radio (e.g. at ~ 20 GHz, e.g., Yusef-Zadeh et al. 2006; Brinkerink et al. 2015) and ~ 100 (~ 400 in extreme cases) in X-rays (2–10 keV, e.g., Baganoff et al. 2003; Neilsen et al. 2013), compared to the quiescent ‘‘non-flare’’ state. We note that, interestingly, these radio and X-ray flares are likely produced from jet (Li, Yuan & Wang 2016; Yusef-Zadeh et al. 2006; Brinkerink et al. 2015). If this is indeed the case, then Sgr A* in its flare state should be included in our quiescent AGN sample, and they are qualified to test the FP of quiescent AGNs. This is examined in Figs. 2 and 5, where the flare state of Sgr A* is shown by the two black asterisks with $L_R \approx 10^{31.5} \text{ erg s}^{-1}$ (10% that of the quiescent state) and $L_X \approx 10^{35.38}$ and $\approx 10^{35.98} \text{ erg s}^{-1}$ (100 and 400 times that of the quiescent state), respectively. Here we only take the enhanced luminosities (compared to the ‘‘non-flare’’ quiescent state) into account, i.e. only these components are of jet origin. Consistent with our expectation, we find that Sgr A* in its flare state agrees nicely with the steep YC05 FP (cf. Eq. 6 and Fig. 2), but disagrees with the original M03 FP (cf. Fig. 5).

5.3.3. Yuan, Yu & Ho (2009) (YYH09)

YYH09 is the first to discover from observational data the existence of a new FP, with $\xi_X \approx 1.22$, in well agreement with the theoretical prediction by YC05. During their sample compilation, YYH09 exclude data from normal LLAGNs, and only include data from quiescent AGNs. Besides, Sgr A* is also excluded from their sample, for reasons listed above. Our work is a natural extension of YYH09. The main improvement to YYH09 is the sample size, which is enlarged from 22 to 75. Besides, the radio emission of several sources, e.g., M31 (Bender et al. 2005; Garcia et al. 2010, $L_X \sim 10^{-10.2} L_{\text{Edd}}$) and M32 (Yang et al. 2015a), is now firmly detected, while in YYH09 their radio emission only has upper limit constraint. The main conclusion remains unchanged, i.e. our enlarged sample confirms the discovery of YYH09.

5.3.4. Dong & Wu (2015) (DW15)

DW15 recently select from the (nearly-)complete flux-limited Polmar survey a sample of 72 AGNs, and combine with a large sample of observational data points of BHBs, to investigate the FP jointly from sub-Eddington to quiescent

⁵ Note that, detailed modelling on the quasi-simultaneous multiband (radio up to X-rays) spectrum of V404 Cyg at such low X-ray luminosity indeed supports that the X-ray emission at the quiescent state is of jet origin (Xie, Yang & Ma 2014).

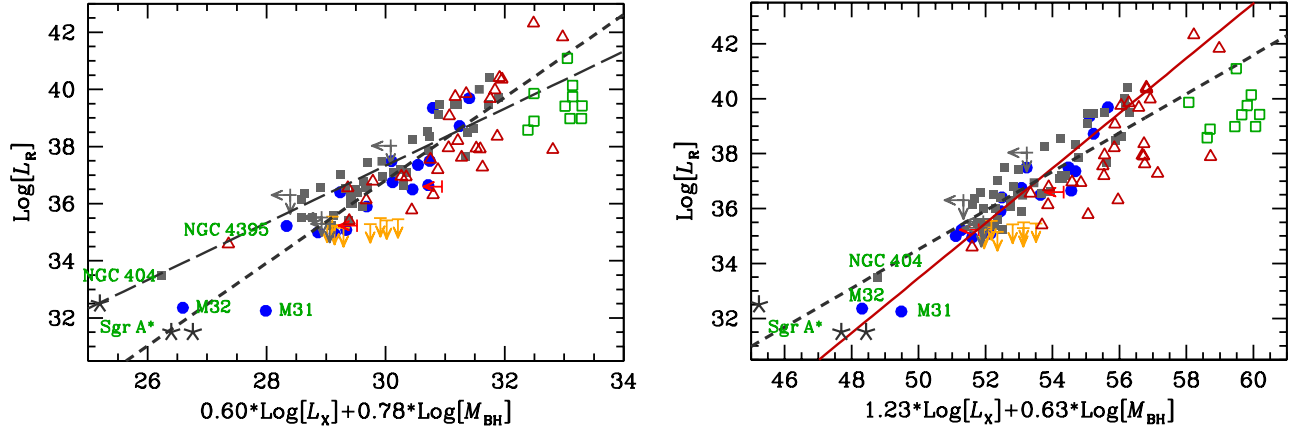

FIG. 5.— Observational data of the combined sample plotted against the M03 FP (left panel, the grey long dashed curve) and the $\xi_X = 1.23$ YC05 FP derived in this work (right panel, the red solid curve). Here the whole sample includes both the quiescent AGNs of this work and also the normal LLAGNs (28 sources from DW15 as representatives; red open triangles). In both panels, symbols and curves are of the same meaning to those in Fig. 2, with one modification, i.e. the quiescent sources shared by both XY and DW15 are now shown as grey filled squares. In addition, the grey dashed curve shows a joint fitting to this combined sample in both panels, where the black hole mass is fixed to $10^{8.5} M_\odot$. In both panels, the green open squares are the 10 M_{BH} -selected M03 AGNs, cf. Fig. 4, and they are taken as representative of brighter AGNs.

systems. They claim those with $L_X \lesssim L_{X,\text{crit}}$ (24 AGNs under a detailed definition of $L_{X,\text{crit}}$) seem to follow the original M03 FP, which disagrees with this work (and YYH09 also).

There are mainly two reasons on such discrepancy. First, notable differences between their sample and ours are observed. Their sample includes the BHBs in their hard and quiescent states, and also Sgr A* in quiescent state. Moreover, because their AGN sample is limited to data from the Polmar survey, the quiescent AGN subsample of DW15 lack sufficient number of sources whose X-ray Eddington ratios are sufficiently low. For the $L_X/L_{\text{Edd}} < 10^{-8}$ regime, there are only three sources in their sample (except Sgr A*), while there are 17 sources in our sample. Several notable faint sources are missed, e.g., M31 (Bender et al. 2005; Garcia et al. 2010, $L_X \sim 10^{-10.2} L_{\text{Edd}}$) and NGC 3115 (Wrobel & Nyland 2012; Wong et al. 2014, $L_X < 10^{-9.5} L_{\text{Edd}}$). These faintest sources, with possibly largest deviation to the original FP, are of crucial importance to reveal the new trend. Secondly, they mainly provide a joint fitting of both normal LLAGNs and quiescent AGNs⁶, while we focus on the quiescent AGNs only here. As illustrated below in Section 5.4, we argue that the small number of quiescent sources in their sample and a joint fitting are the reasons for the discrepancy between their result and ours.

5.4. Disadvantages of a joint fitting of both normal LLAGNs and quiescent AGNs

We here discuss the disadvantages of a joint fitting of a sample that includes both normal LLAGNs and quiescent AGNs, especially when the steeper correlation is statistically insignificant as the sample lack sufficient number of dimmest sources. For this purpose, we consider a combined AGN sample, including not only the quiescent AGNs of this work (hereby named as the XY sample) but also 28 normal LLAGNs of DW15 (red open triangles in Fig. 5. Note that, except for Sgr A*, the rest 44 AGNs are selected into the XY sample). We note that it has been known for years that

some sources do not follow the original M03 FP (e.g., Li et al. 2008; de Gasperin et al. 2011 for AGNs, and Coriat et al. 2011 for BHBs. cf. Introduction). Consequently, the exact values of the fitting depend on both sample selection and statistical methods, as noted in Kording et al. (2006) and demonstrated in Sec. 4.

We analysis the combined sample through the Bayesian approach. The correlation indexes now read as,

$$\xi_X = 0.87^{+0.04}_{-0.04}, \quad \xi_M = 1.29^{+0.09}_{-0.08}, \quad c = -8.05^{+1.48}_{-1.50}. \quad (15)$$

Note that the value of ξ_X is between the result of DW15 and the present work shown in Section 4. This indicates that the value of ξ_X is somewhat sensitive to the fraction of quiescent sources included in the sample, more fraction of quiescent ones will make its value larger and the radio/X-ray correlation slope steeper. This is consistent with our expectation.

Now we do the statistical analysis by another way. We fix the value of ξ_X and test two-parameter fittings of the combined sample. We find that both the $\xi_X \approx 0.6$ (M03-like) correlation and the $\xi_X \approx 1.23$ (YC05-like) correlation could provide almost equally good (or bad) fits to the combined sample, i.e. both of which leads to relatively similar reduced χ^2 values. Consequently it is difficult to judge from statistical instead of physical point of view which fitting is better.

Fig. 5 shows the data points of the combined sample plotted against the M03 FP (left panel; cf. M03) and the YC05 FP (right panel; cf. Eq. 6). For clarity, the quiescent sources shared by both XY and DW15 are now shown as grey filled squares. For comparison, we show in the two panels the fitting of this combined sample (Eq. 15) as grey dashed curve, where M_{BH} is set to $10^{8.5} M_\odot$. Based on the above fitting results as well as the direct comparison between the two panels, we can understand the reason for the discrepancy between this work (and other similar ones) and DW15 (and other similar ones). The first reason has been pointed out already below Eq. 15, i.e., the correlation index will be determined by the fraction of quiescent sources (or equivalently normal sources) whose L_X are far away from $L_{X,\text{crit}}$ included in the sample. The second reason is that, as shown in Fig. 5, because the luminosity scales as $L_{R,X} \propto L_{R,X}/L_{\text{Edd}} \times M_{\text{BH}}$ and the differences in M_{BH} is sufficiently large (by ~ 3 orders of magnitude) in both quiescent and normal low-luminosity AGNs, the quiescent

⁶ We note that, since their quiescent subsample also includes data points from BHBs and Sgr A*, a fitting of such subsample, as shown in the bottom-right panel of Fig. 1 in DW15, will be misleading also. Indeed, as shown in their Fig. 2, the subsample of quiescent AGNs with similar BH mass do hint on a much steeper radio/X-ray relationship.

sources will mix up with those normal ones in L_X and L_R . Consequently, quiescent sources that are not dim enough (in L_X/L_{Edd}) will only contribute to the scatter of the original M03 FP, and the YC05 FP will be obscured.

FIG. 6.— The $L_R/L_{\text{Edd}} - L_X/L_{\text{Edd}}$ relationship of the combined sample. The meaning of the symbols is the same as that in Fig. 5. The solid and the dashed curves represent, respectively, the YC05 FP (cf. Eq. 6) and the original M03 FP, where the black hole mass is fixed to $10^{8.5} M_\odot$.

We argue that since the YC05 prediction is based on the difference in L_X/L_{Edd} rather than L_X , the correct way to examine this prediction is to investigate the sample only consisting of sources with $L_X/L_{\text{Edd}} \lesssim 10^{-6}$. This is also more physical since the underlying physics is determined by L_X/L_{Edd} instead of L_X . A M_{BH} -free subsample (cf. Section 4.2) will help to solve this problem. Indeed, from the M_{BH} -selected sample, the quiescent AGNs do follow a radio/X-ray correlation that is much steeper compared to that followed by those normal (LL)AGNs. This result is clearly shown in Fig. 4.

Based on this consideration, we propose that a better way to analyze the correlation is to replace L_R and L_X with L_R/L_{Edd} and L_X/L_{Edd} , and investigate the FP under a revised three-dimensional ($\log(L_R/L_{\text{Edd}})$, $\log(L_X/L_{\text{Edd}})$, $\log(M_{\text{BH}})$) space. One notable advantage of this new space is that, objects with different Eddington ratios will be separated automatically. For a demonstration of this advantage, we show in Fig. 6 the $L_R/L_{\text{Edd}} - L_X/L_{\text{Edd}}$ relationship of the combined sample, with additional 10 M_{BH} -selected M03 AGNs. From this plot, we can see clearly that the correlation slope above and below $L_X/L_{\text{Edd}} \sim 10^{-6}$ is different. The quiescent sources do follow a steeper radio/X-ray correlation compared to that of normal LLAGNs, in agreement with YC05 and our finding in the present paper. This new parameter space will be very helpful to the investigation of FP at different luminosity regimes (in Eddington unit), where a change in the FP may be observed, as a consequence of the change in accretion mode at that luminosity regime (e.g. Xie & Yuan 2012, 2016; Yuan & Narayan 2014; Yang et al. 2015b).

As a preliminary test, we consider our whole quiescent AGN sample (the XY sample). The scatter of each quantity is fixed to 0.3 dex, for the sake of simplicity. Under the Bayesian approach we find that,

$$\log(L_R/L_{\text{Edd}}) = 1.29^{+0.07}_{-0.06} \log(L_X/L_{\text{Edd}}) + 0.89^{+0.10}_{-0.09} \log M_{\text{BH}} - 7.61^{+0.87}_{-0.89}. \quad (16)$$

The scatter in L_R/L_{Edd} is 0.82 dex. This result can be re-

written as $L_R \propto L_X^{1.29} M_{\text{BH}}^{0.60}$.

5.5. The distribution of Radio-loudness parameter R_X versus Eddington ratio in faint AGNs with $L_X/L_{\text{Edd}} \lesssim 10^{-6}$

It is widely known that LLAGNs tend to be radio-loud systematically, and the radio-loudness parameter, defined as $R_X = L_R/L_X$, scales inversely with Eddington ratios $L_{\text{bol}}/L_{\text{Edd}}$ (among others see e.g., Ho 2008; Nyland et al. 2016), where L_{bol} is the bolometric luminosity. We note that the FP can be re-written as, $R_X \propto L_X^{\xi_X - 1}$. If L_{bol} scales positively with L_X (likely a reasonable assumption), then the YC05 FP, with $\xi_X \approx 1.23 > 1$, predicts that quiescent AGNs follow a positive $R_X - L_{\text{bol}}/L_{\text{Edd}}$ relationship, opposite to those normal LLAGNs.

FIG. 7.— Distribution of radio-loudness parameter R_X versus Eddington ratio $L_{\text{bol}}/L_{\text{Edd}}$, where the bolometric luminosity is estimated as, $L_{\text{bol}} = 16 L_X$. The meaning of the symbols is the same as that in Fig. 5. Note that those black open circles are sources whose L_X and L_R are upper-limit constraints, i.e. their R_X is actually un-constrained. The solid and the dashed curves represent, respectively, the YC05 FP (cf. Eq. 6) and the original M03 FP, where the black hole mass is fixed to $10^{8.5} M_\odot$.

Fig. 7 illustrates the distribution of radio-loudness parameter R_X versus Eddington ratios for both quiescent AGNs and normal LLAGNs. For normal LLAGNs, we take those from DW15 as representatives. Following Ho (2008), we estimate the bolometric luminosity simply from the X-ray luminosity, i.e. $L_{\text{bol}} = 16 L_X$. Note that those black open circles are sources whose L_X and L_R are upper-limit constraints, i.e. their R_X is actually un-constrained. The black solid and long-dashed curves, respectively, show the results derived from the YC05 FP and the original M03 FP, where the BH mass is fixed to $10^{8.5} M_\odot$. From this figure, the possible turnover at Eddington ratio $L_{\text{bol}}/L_{\text{Edd}} = 10^{-5.5}$ (or equivalently $L_X/L_{\text{Edd}} = 10^{-6.5}$; see also Yang et al. 2015b for this value, as constrained by the X-ray spectral properties in AGNs and BHBs.) is admittedly less evident. More observations of quiescent AGNs with $L_X/L_{\text{Edd}} \lesssim 10^{-8}$ (or Eddington ratio $L_{\text{bol}}/L_{\text{Edd}} \lesssim 10^{-7}$) are urged to examine this new trend in future.

6. SUMMARY

The Fundamental Plane provides a direct evidence on the disk-jet connection (e.g. M03; Falcke et al. 2004; Merloni et al. 2006; YYH09). One remaining question under active debate is whether or not those very faint accretion systems (i.e., L_X/L_{Edd} below a critical value $\sim 10^{-6}$) follow the original M03 FP or the steeper (in sense of the radio/X-ray

correlation slope) YC05 relationship. Many works favour the YC05 FP (e.g., Wu, Yuan & Ho 2007; Pellegrini et al. 2007; Wrobel, Terashima & Ho 2008; YYH09; de Gasperin et al. 2011; Younes et al. 2012; Reynolds et al. 2014), while several others favour an universal FP extending down to quiescent/faint systems (Gallo et al. 2006, 2014; Corbel, Koerding & Kaaret 2008; DW15). In this work we re-visit this problem. For this aim, the quality of the data (mainly the radio data) of BHBs is not satisfactory thus the conclusion based on that is not convincing, as we argue in Section 5.3.1. Therefore we focus on quiescent AGNs, paying special attention to the radio/X-ray correlation slope ξ_X . Compared to previous studies, in our work we gather from literature as many faint AGNs as possible thus our sample is the largest to date, with 5 sources fainter than $10^{-9}L_{\text{Edd}}$ in X-rays (Fig. 1). As we show in the paper, these faint sources are crucial to discriminate different correlations. Our main results are summarized as follows,

- Based on our quiescent AGN sample, we find that quiescent AGNs follow a steeper FP compared to M03 FP. The radio/X-ray correlation slope $\xi_X \approx 1.23$, in good consistency with the prediction of YC05 (Fig. 2).
- To further focus on the radio/X-ray correlation but eliminate any possible contamination of the black hole mass, we create a sub-sample in which the black hole mass is similar. For such a M_{BH} -free sub-sample, we find that the value of $\xi \approx 1.36$ (Fig. 4).
- We have further explored the reasons for the discrepancy between the present result and some previous ones. We find that, for the combined AGN sample that includes sources of both $L_X/L_{\text{Edd}} \lesssim 10^{-6}$ and $L_X/L_{\text{Edd}} \gtrsim 10^{-6}$, the value of ξ_X is ≈ 0.87 (Eq. 15), which is between 0.6 and ~ 1.2 – 1.3 . It is expected that the exact value of ξ_X in general will be determined by the fraction of quiescent (or equivalently normal) sources in the sample. Put it in another way, we find that the $\xi_X \approx 0.6$ correlation and the $\xi_X \approx 1.23$ correlation provide almost equally good (or bad) fits to the combined sample, and it is difficult to judge from statistical instead of physical point of view which fitting

is better. We thus argue this approach is not the best way to examine the correlation at quiescent regime. In the traditional approach, unless the quiescent sources are extremely faint (in L_X/L_{Edd}), we cannot separate them from normal ones, since they are mixed up with in L_X and L_R due to the large range in black hole mass. Consequently, quiescent sources will only contribute to the scatter of the original FP (the left panel of Fig. 5).

- Given the above reasons, we propose that a better way to investigate the Fundamental Plane is to use a revised three-dimensional space spanned by $\log(L_R/L_{\text{Edd}})$, $\log(L_X/L_{\text{Edd}})$, and $\log(M_{\text{BH}})$. Physically, parameters L_R/L_{Edd} and L_X/L_{Edd} have more direct connections to the accretion/jet physics. One notable advantage of this new space is that, objects with different Eddington ratios (thus may relate to different accretion regimes) are separated automatically. As shown in the Figs. 4&6, there is clearly a “break” in the $L_R/L_{\text{Edd}} - L_X/L_{\text{Edd}}$ correlation at a critical luminosity $L_X/L_{\text{Edd}} \sim 10^{-6}$, below which the correlation is steeper, consistent with YC05 and YYH09.

ACKNOWLEDGEMENTS

We thank Drs. Qingwen Wu and Ai-Jun Dong for helpful discussions and comments, and the referee for valuable suggestions that improve our analysis. FGX thanks Drs. Zhaoming Gan, Doosoon Yoon and Zhen Yan for the help on Python, and Drs. Zhao-Zhou Li and Shi-Yin Shen for the help on Bayesian regression analysis. FGX and FY are supported in part by the National Program on Key Research and Development Project of China (Grant Nos. 2016YFA0400804 and 2016YFA0400704), the Youth Innovation Promotion Association of Chinese Academy of Sciences (CAS) (id. 2016243), the Natural Science Foundation of China (grants 11573051, 11633006 and 11661161012), the Key Research Program of Frontier Sciences of CAS (No. QYZDJ-SSW-SYS008). This work has made extensive use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration (NASA).
